

| String | |
|--|-----------|
| •Strings are just a series of characters (e.g., alpha, numeric, punctuation etc.) | |
| •A string can be treated as one entity. - Online example: "string1.py" def fun (aString): print aString | |
| # MAIN aString = "Goodbye cruel world!" fun (aString) | |
| Or the individual elements (characters) can be accessed via ar index. Online example: "string2.py" Note: A string with 'n' elements has an index from 0 to (n-1) # MAIN | 1 |
| aString = "hello" print (aString[1]) print (aString[4]) | James Tam |

Strings Are Immutable

•Even though it may look a string can change they actually cannot be edited.

- Online example: "string3.py"

MAIN

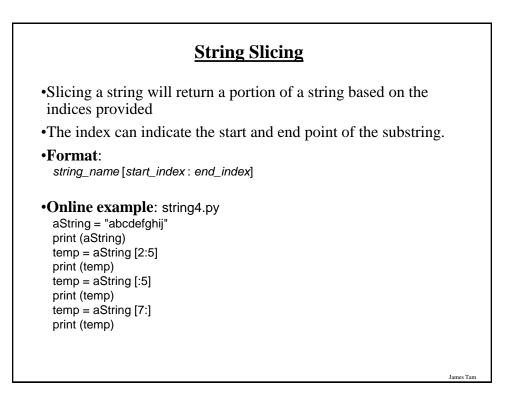

aString = "good-bye" print (aString) aString = "hello" print (aString) aString[0] = "G" #

Error

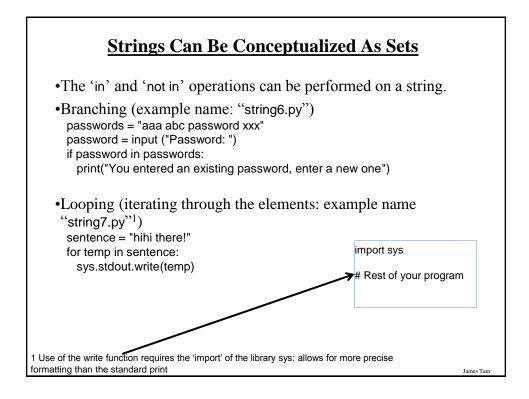

Substring Operations

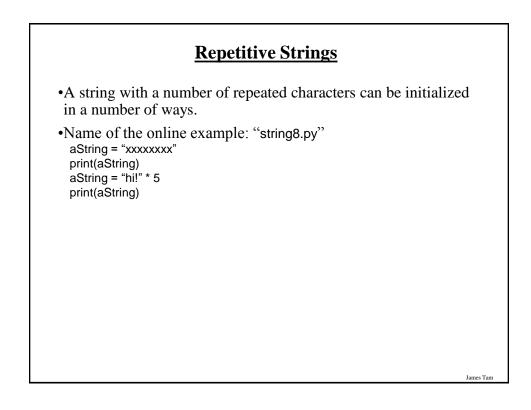

James Tarr

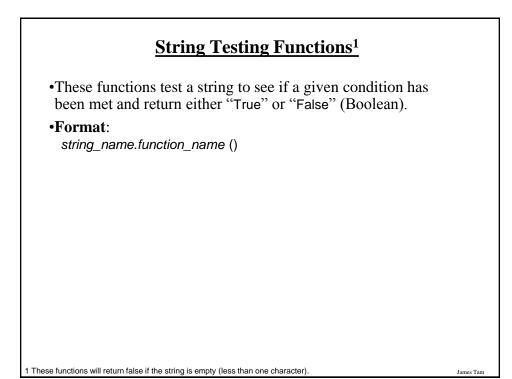

- •Sometimes you may wish to extract out a portion of a string. -E.g., Extract out "James" from "James T. Kirk, Captain"
- •This operation is referred to as a 'substring' operation in many programming languages.
- •There are two implementations of the substring operation in Python:
 - String slicing
 - String splitting

| String Splitting | |
|--|-----------|
| Divide a string into portions with a particular character determining where the split occurs. The string "The cat in the hat" could be split into individual words - "The" "cat" "in" "the" "hat" Format: string_name.split ("<character in="" li="" split")<="" the="" used=""> </character> | |
| •Online example: string5.py aString = "man who smiles" one, two, three = aString.split() # Default character is a space print (one) print (two) print (three) aString = "Tam, James" last, first = aString.split(',') print (first, last) | |
| | James Tam |

| Boolean Function | Description |
|---------------------|--|
| isalpha () | Only true if the string consists only of alphabetic characters. |
| isdigit () | Only returns true if the string consists only of digits. |
| isalnum () | Only returns true if the string is composed only of alphabetic characters or numeric digits. |
| islower () | Only returns true if the alphabetic characters in the string are all lower case. |
| isspace () | Only returns true if string consists only of whitespace characters (" ", "\n", "\t") |
| isupper () | Only returns true if the alphabetic characters in the string are all upper case. |

Applying A String Testing Function

```
Name of the online example: "string9.py"
ok = False
while (ok == False):
temp = input ("Enter numbers not characters: ")
ok = temp.isdigit()
if (ok == False):
print(temp, "is not a number")
else:
print("done")
num = int (temp)
num = num + num
print(num)
```

Functions That Modify Strings

James Tarr

•These functions return a modified version of an existing string (leaves the original string intact). Ws = sp, tab, enter

| Function | Description |
|---------------|---|
| lower () | Returns a copy of the string with all the alpha characters as lower case (non-alpha characters are unaffected). |
| upper () | Returns a copy of the string with all the alpha characters as upper case (non-alpha characters are unaffected). |
| strip () | Returns a copy of the string with all leading and trailing whitespace characters removed. |
| lstrip () | Returns a copy of the string with all leading (left) whitespace characters removed. |
| rstrip () | Returns a copy of the string with all trailing (right) whitespace characters removed. |
| lstrip (char) | Returns a copy of the string with all leading instances of the character parameter removed. |
| rstrip (char) | Returns a copy of the string with all trailing instances of the character parameter removed. |

Example Uses Of Functions That Modify Strings

Name of the online example: string10.py

aString = "talk1! AbouT" print(aString) aString = aString.upper () print(aString)

aString = "xxhello there" print(aString) aString = aString.lstrip ('x') print(aString) aString = "xxhellx thxrx" aString = aString.lstrip ('x') print(aString)

| Function | Description | |
|--------------------------------|---|--|
| endswith (substring) | A substring is the parameter and the function returns true only if the string ends with the substring. | |
| startswith (substring) | A substring is the parameter and the function returns true only if the string starts with the substring. | |
| find (substring) | A substring is the parameter and the function returns the lowest index in the string where the substring is found (or -1 if the substring was not found). | |
| replace (oldstring, newstring) | The function returns a copy of the string with all instances of 'oldstring' replace by 'newstring' | |

James Tarr

Examples Of Functions To Search Strings

Name of the online example: string11.py

temp = input ("Enter a sentence: ")
if not ((temp.endswith('.')) or (temp.endswith('!')) or (temp.endswith ('?'))):
 print("Not a sentence")

temp = "XXabcXabcabc"
index = temp.find("abc")
print(index)

temp = temp.replace("abc", "Abc")
print(temp)

List

James Tarr

- •In many programming languages a list is implemented as an array.
- •Python lists have many of the characteristics of the arrays in other programming languages but they also have many other features.
- •This first section will talk about the features of lists that are largely common to arrays.

Example Problem

•Write a program that will track the percentage grades for a class of students. The program should allow the user to enter the grade for each student. Then it will display the grades for the whole class along with the average.

Why Bother With Composite Types?

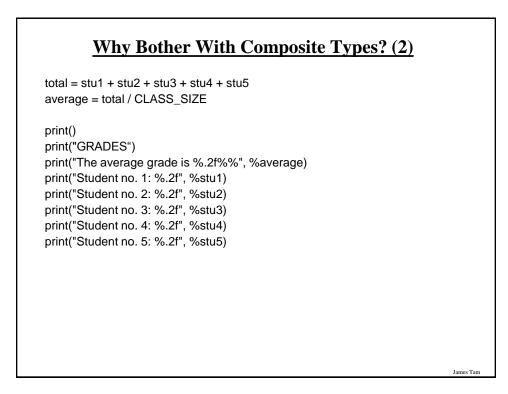

James Tan

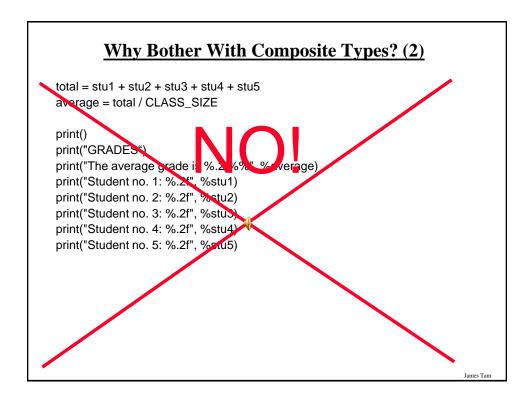

James Tam

•Name of the example program: classList1.py

 $CLASS_SIZE = 5$

stu1 = float(input ("Enter grade for student no. 1: "))
stu2 = float(input ("Enter grade for student no. 2: "))
stu3 = float(input("Enter grade for student no. 3: "))
stu4 = float(input("Enter grade for student no. 4: "))
stu5 = float(input("Enter grade for student no. 5: "))

<u>What Were The Problems With</u> <u>The Previous Approach?</u>

•Redundant statements.

•Yet a loop could not be easily employed given the types of variables that you have seen so far.

What's Needed

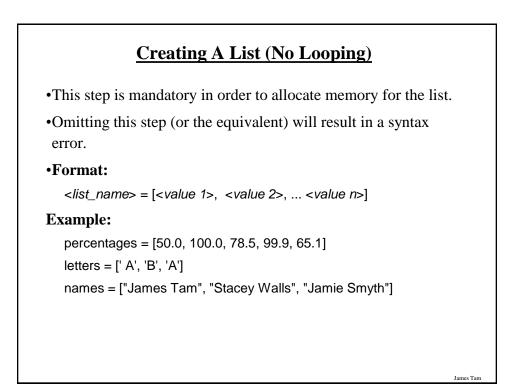

James Tarr

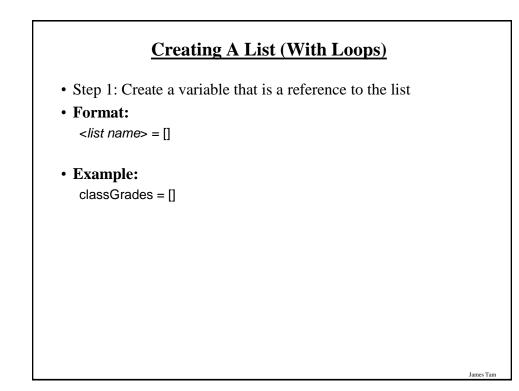

James Tam

•A composite variable that is a collection of another type.

- The composite variable can be manipulated and passed throughout the program as a single entity.
- At the same time each element can be accessed individually.

•What's needed...a list!

Creating A List (With Loops: 2)

•Step 2: Initialize the list with the elements

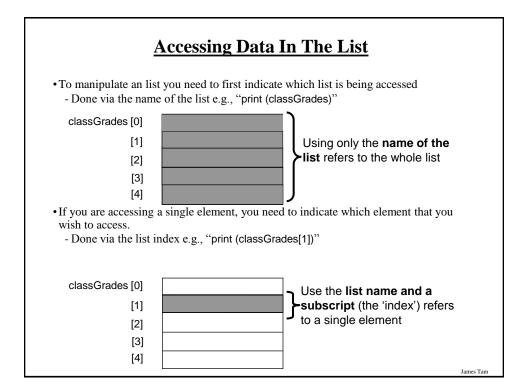

•General format:

- Within the body of a loop create each element and then append the new element on the end of the list.

•Example:

for i in range (0, 5, 1):

classGrades.append (0)

Programming: Composite types (lists, strings, tuples, classes)

James Tarr

Revised Version Using A List

•Name of the example program: classList2.py

```
CLASS_SIZE = 5
```

def read(classGrades):

total = 0

for i in range (0, CLASS_SIZE, 1):

Because list indices start at zero add one to the student number. temp = i + 1

James Tarr

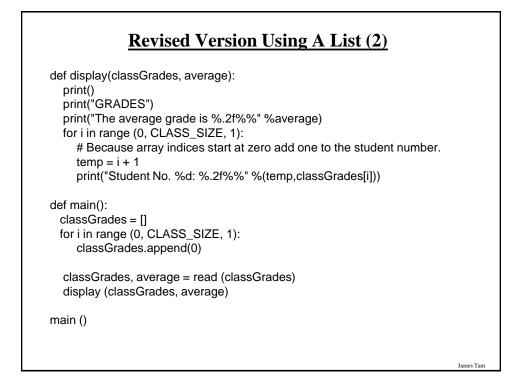

print("Enter grade for student no.", temp, ":")

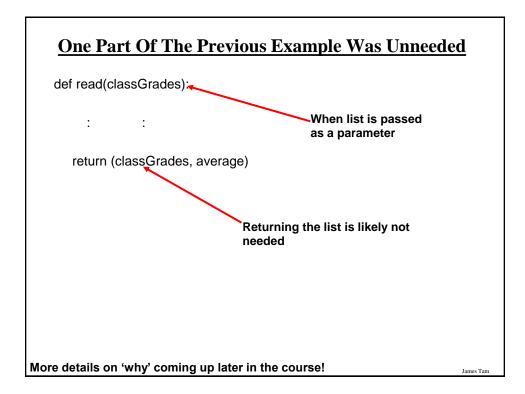

classGrades[i] = float(input (">"))

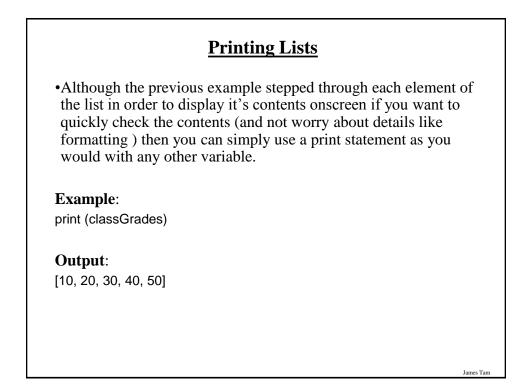

total = total + classGrades[i]

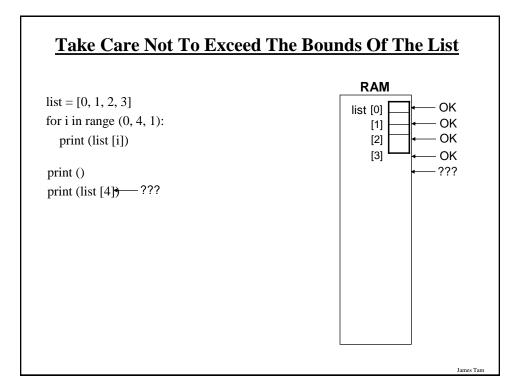

average = total / CLASS_SIZE

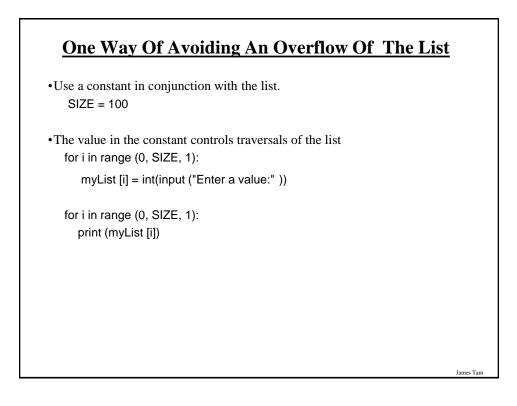

return (classGrades, average)

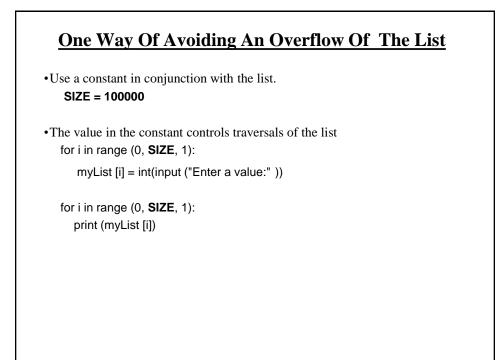

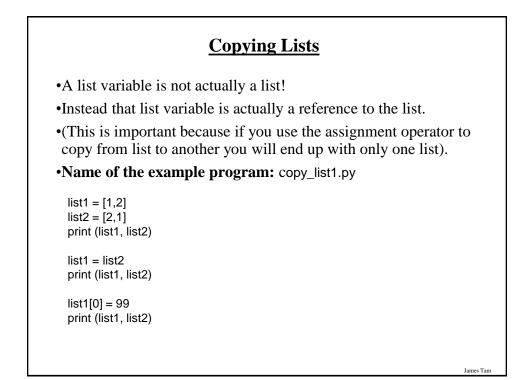

James Tarr

Copying Lists (2)

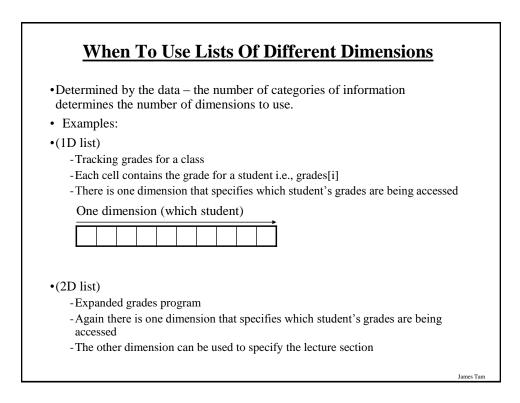

•To copy the elements of one list to another a loop is needed to copy each successive elements.

•Name of the example program: copy_list2.py

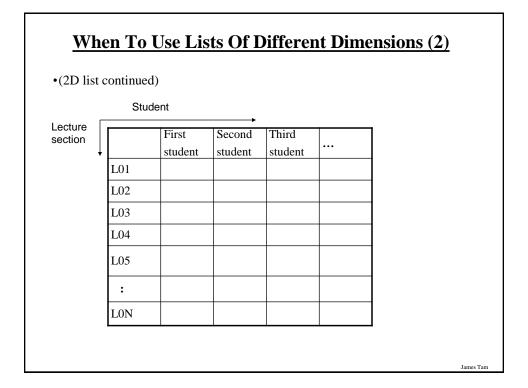

list1 = [1,2,3,4] list2 = []

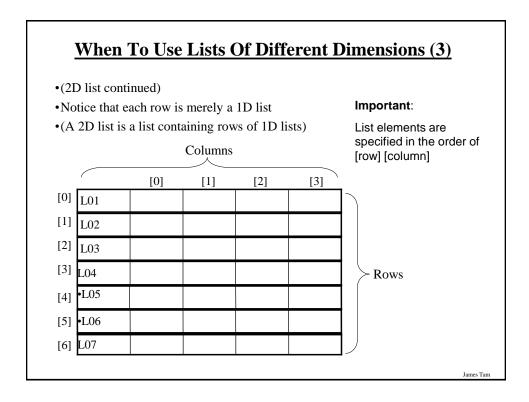

for i in range (0, 4, 1): list2.append(list1[i])

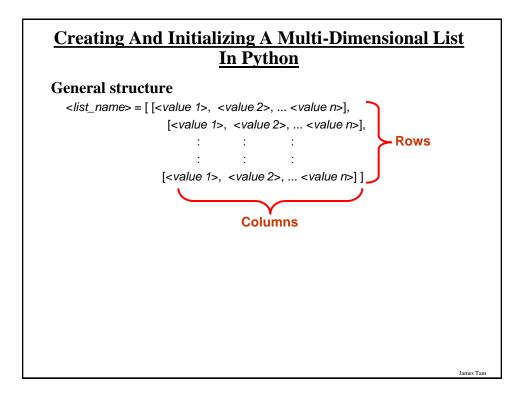

print list1, list2 list1[1] = 99 print (list1, list2)

James Tan

Creating And Initializing A Multi-Dimensional List In Python (2) Mare of the example program: display_list.pr matrix = [[0, 0, 0], [1, 1, 1], [2, 2, 2], [3, 3, 3]] for r in range (0, 4, 1): print (matrix[r]) for r in range (0,4, 1): for c in range (0,3,1): sys.stdout.write(str(matrix[r][c])) print()

<u>Creating And Initializing A Multi-Dimensional List</u> <u>In Python (3)</u>

General structure (Using loops):

•Create a variable that refers to a 1D list. The outer loop traverses the rows. Each iteration of the outer loop creates a new 1D list. Then the inner loop traverses the columns of the newly created 1D list creating and initializing each element in a fashion similar to how a single 1D list was created and initialized.

•Example (Using loops):

aGrid = [] for r in range (0, 3, 1): aGrid.append ([]) for c in range (0, 3, 1): aGrid[r].append (" ")

Create a reference to the list
Outer loop runs once for each row
Create a row (a 1D list)
Inner loop runs once for each column
Create and initialize each element (1D list)

James Tarr

James Tam

Example 2D List Program: A Character-Based Grid

•Name of the example program: simple_grid.py

import sys

aGrid = []

for r in range (0,2,1): aGrid.append ([]) for c in range (0,3,1): aGrid[r].append (str(r+c))

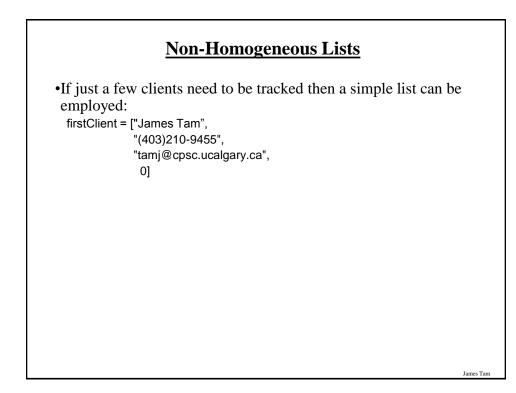

```
for r in range (0,2,1):
  for c in range (0,3,1):
    sys.stdout.write(str(aGrid[r][c]))
  print()
```

List Elements Need Not Store The Same Data Type

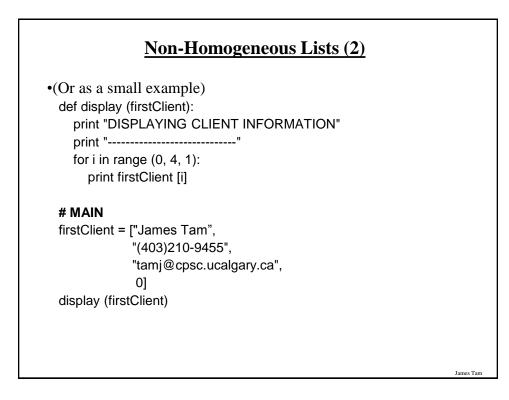

•What if different types of information needs to be tracked in the list?

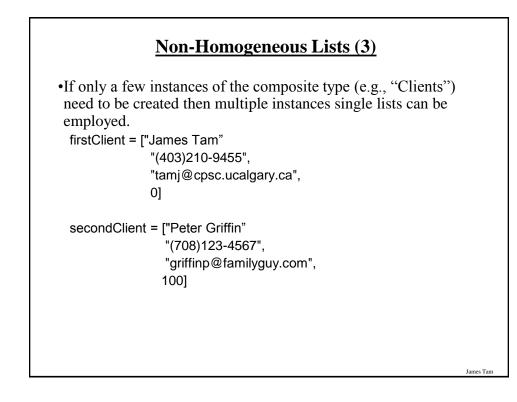

Example, storing information about a client:

- •Nameseries of characters
- Phone number ... numerical or character
- •Email addressseries of characters
- •Total purchases made ...numerical or character

James Tarr

Small Example Programs Using Lists

•Names of the example programs: -list1.py (concatenation and repetition)

- list2.py (membership)

| Operation name | Operator | Description |
|----------------|----------|--|
| Indexing | 0 | Access a list element |
| Concatenation | + | Combine lists |
| Repetition | * | Concatenate a repeated number of times |
| Membership | in | Query whether an item is a member of a list |
| Membership | not in | Query whether an item is not a member of a list |
| Length | len | Return the number of items in a list |
| Slicing | [:] | Extract a part of a list |

Programming: Composite types (lists, strings, tuples, classes)

Examples: Concatenation, Repetition, Length

Name of the online example: list_concatenation_repetition_length.py

list1 = [1, 2.0, "foo"] list2 = [[1,2,3], "bar"] print(list1) print(len(list1)) list1 = list1 * 2 print(len(list1)) print(len(list1)) print(list1) list3 = list1 + list2 print(list3)

Examples: Membership

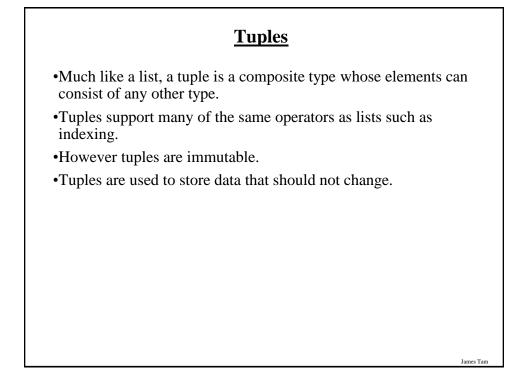

James Tarr

James Tam

Name of the online example: list_membership.py

```
print("Example 1: ")
recall_list = ["vpn123", "NCC-75633", "gst7"]
item = input ("Product code to check for recall: ")
if item in recall_list:
    print("Your product was on the recall list, take it back")
else:
    print("You're safe")
print()
print("Example 2:")
days = ["Sun", "Mon", "Tue", "Wed", "Thur", "Fri", "Sat"]
for temp in days:
    print(temp)
```

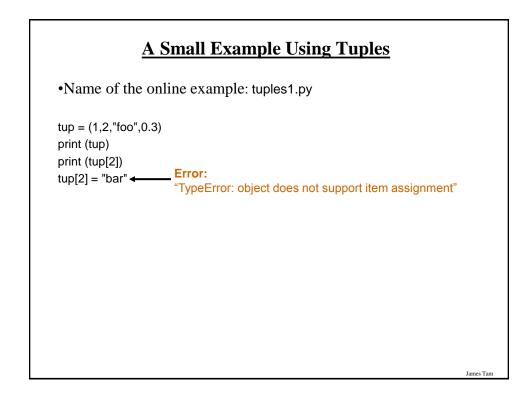

| Operation | Format | Description |
|-----------|----------------------------|--|
| Append | list_name.append (item) | Adds a new item to the end of the list |
| Insert | list_name.insert (i, item) | Inserts a new item at index 'i' |
| Sort | list_name.sort () | Sorts from smallest to largest |
| Reverse | list_name.reverse () | Reverses the current order of the list |
| Count | list_name.count (item) | Counts and returns the number of occurrences of the item |

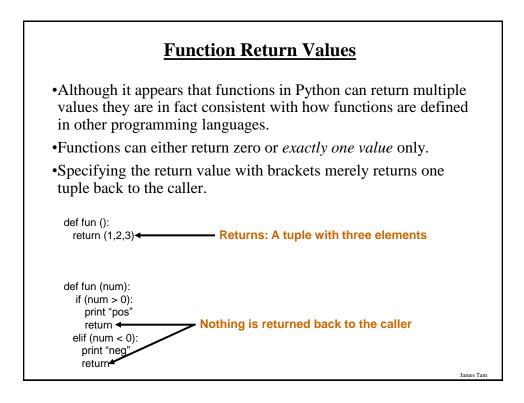

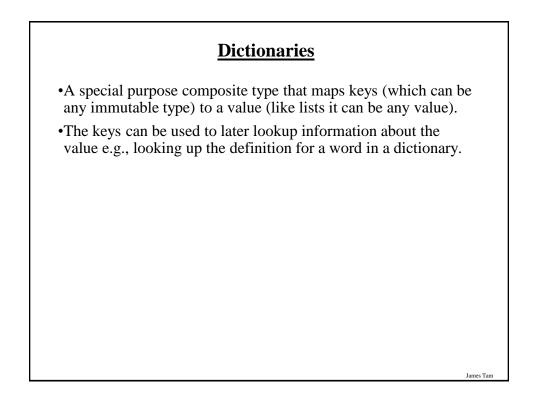

Creating Tuples

•Format: tuple_name = (value¹, value²...valueⁿ)

•Example: tup = (1,2,"foo",0.3)

Small Example Programs Using Dictionaries

•The names of the online examples:

- dictionary1.py (creating dictionaries)

- dictionary2.py (deleting entries from the dictionary, checking for membership)

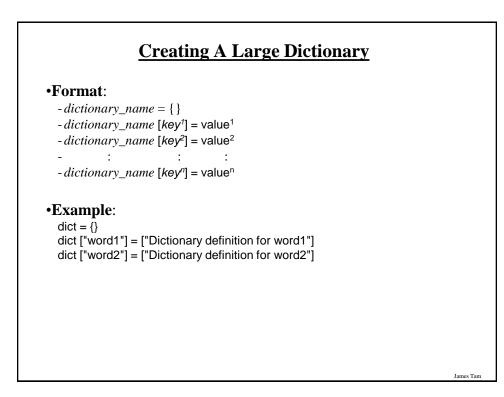

Creating A Small Dictionary

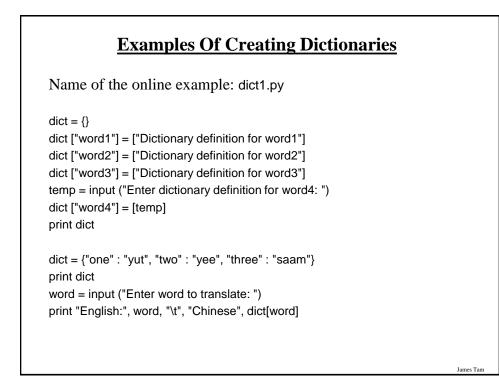

James Tam

James Tam

•**Format** (defining the entire dictionary all at once) <*dictionary_name>* = {*key*¹:*value*¹, *key*²:*value*²...*key*ⁿ:*value*ⁿ}

•Example: (defining the entire dictionary all at once) dict = {"one":"yut", "two":"yee", "three":"saam"}

Removing Dictionary Entries

•**Format**: - del <*dictionary_name*> [*key*]

•Example: del dict ["one"]

Example: Deletion And Checking For Membership

James Tarr

James Tam

Name of the online example: dict2.py

dict = {}
dict ["one"] = "Sentence one"
dict ["two"] = "Sentence two"
dict ["three"] = "Sentence three"

if "one" in dict: print("key one is in the dictionary")

del dict["one"]
if "one" not in dict:
 print("key one is NOT in the dictionary")

Extra Practice

String:

- Write the code that implements the single operations (e.g., splitting) or functions (e.g., alpha)

List operations:

- Calculate the average of the elements of a numerical list

- Find the min and max elements of a numerical list

You Should Now Know

James Tan

- •What is the difference between a mutable and an immutable type
- •How strings are actually a composite type
- •Common string functions and operations
- •Why and when a list should be used
- •How to create and initialize a list
- •How to access or change the elements of a list
- •Copying lists: How does it work/How to do it properly
- •When to use lists of different dimensions
- •How to use the 'in' operator in conjunction with lists
- •How a list can be used to store different types of information (non-homogeneous composite type)

You Should Now Know (2)

•Common list operations and functions

•How to define an arbitrary composite type using a class

•What is a tuple and how do they differ from other composite types

You Should Now Know (2)

James Tan

James Tam

•How to create a tuple and access the elements

•Why functions at most return a single value

•What is a dictionary and when can they can be used

•How to create a dictionary, access and remove elements
